CENTER DISCUSSION PAPER NO. 1021

**A Two-Tiered Demographic System: “Insiders” and
“Outsiders” in Three Swabian Communities, 1558-1914**

Notes: Center discussion papers are preliminary materials circulated to stimulate discussion and critical comments.

We gratefully acknowledge financial support from the Economic and Social Research Council of Great Britain; the Leverhulme Trust; and the Economic Growth Center (Yale University). Markus Küpker and Janine Maegraith provided invaluable research assistance. We are grateful to Adèle Rossouw and Marian Schmidt for additional help. For comments and suggestions we thank seminar participants at INED, Queen’s University (Kingston), UCLA, the University of Copenhagen, and Williams College. This paper is part of a larger ongoing project; for detailed background information on the communities in question, see Ogilvie, Küpker and Maegraith (2009), and for a more formal treatment of population and economic shocks, see Guinnane and Ogilvie (2008).

Abstract

This paper presents first results from a project to reconstitute the demographic behavior of three villages in Württemberg (southern Germany) from the mid-sixteenth to the early twentieth century. Using high-quality registers of births, deaths, and marriages, and unusual ancillary sources, we improve on the family-reconstitution techniques pioneered by Louis Henry and applied to good effect by the Cambridge Group and other scholars. This paper focuses on simple, standard demographic measures, in order to provide a broad overview and support comparisons with other places. An extreme system of demographic regulation operated in these Württemberg communities until around 1870. This regulation created a two-tiered demographic system. A group of “insiders” were able to marry, and experienced both high marital fertility and high infant and child mortality. A second group of “outsiders” were prevented from marrying. Many, especially the males, left the community; those who stayed contributed to growing illegitimacy and associated levels of infant and child mortality that were even higher than for the offspring of “insiders”.

Keywords: Fertility, Mortality, Nuptiality, European marriage pattern, institutions, community, *politische Ehekonsens*, Germany, Württemberg, proto-industry

JEL codes: N33, J12, J13, K0, O17

Recent research on long-run economic development stresses the role of population behavior in fostering the accumulation of both physical and human capital.¹ This interest highlights the need for careful empirical analysis of demographic behavior in the past. Much current research on economic growth relies too heavily either on stylized facts that mask interesting and informative variation, or on research on a relatively narrow part of Europe, or both. This paper reports first results from a project that delves into the specifics of demographic behavior in three south German villages between 1558 and 1914. It spans the onset of the demographic transition from high to low fertility, and the industrial revolution that transformed economic techniques and practices. This paper does not address the wider economic growth literature, but the type of research it reports is crucial to understanding those transformations.

Compared to England and France, the two European societies whose historical demography is best known, our communities were poor and economically stagnant. They were also characterized by local controls on decision-making, especially by poorer social strata, that shaped the demographic outcomes we discover. We argue that this system divided the population into two groups, which we call “insiders” and “outsiders.” Insiders were allowed to marry, and then experienced high rates of marital fertility and infant and child mortality. Just why fertility and mortality were so high awaits further research, but it clearly reflects low incidence of breastfeeding, which may in turn reflect the opportunity cost of time for “insider” women.² Outsiders either left the community or remained but were not allowed to marry; their children, if any, were illegitimate and experienced even higher levels of mortality than the children of “insiders”.

Demographic decisions in Württemberg, as in many other parts of Central Europe before the late nineteenth century, took place in the context of the *politische Ehekonsens*, the requirement that a couple obtain permission from the local authorities before they could marry (Knodel 1967; Matz 1980; Ehmer

¹ Galor and Weil (2000) is the key reference in “unified growth theory,” the most influential strand of recent theoretical work on long-run growth. Galor (2011) discusses more recent contributions. Guinnane (2011) discusses the demographic transition, stressing weaknesses in the way the growth-theoretical literature interprets the historical evidence.

² For suggestive evidence to this effect, see Ogilvie (2003), 196-200; Medick (1996), 359-60, 368-9.

1991; Mantl 1997, 1999; Ogilvie 1995). The historiography has taken conflicting views of the *Ehekonsens*. Some scholars have argued that it was enforced to a considerable extent, leading to restrictions on marriage, unusually high levels of illegitimacy, and out-migration by those denied a place as a married person entitled to head their own independent household in the local economy. Others have claimed that the *politische Ehekonsens* was merely formal, could not be enforced in practice, and therefore played no appreciable role in demographic decisions. Our sources allow us to compare behavior before and after the repeal. The results show that the former view is correct: when the *politische Ehekonsens* was abolished we see immediate and dramatic increases in the number of marriages as well as sharp reductions in illegitimacy. These changes show that the *politische Ehekonsens* was a binding constraint on marriage decisions before the repeal, with knock-on consequences for fertility, infant mortality, and the entire demographic system.

This paper draws most of its evidence from two sources. The more important is the family reconstitution for each of the three communities. Family reconstitution starts with nominative registers of births, deaths, and marriages, and then links items of information within and between individuals in such a way as to enable computation of key demographic parameters. For example, by linking a person's birth entry to his death entry, we know how old he was when he died. Our family reconstitutions follow the technique pioneered by Louis Henry and applied by the Cambridge Group and others (see, for example, Wrigley et al. 1997). But we have unusual, additional sources – census-type listings, tax registers, property lists and inventories – that permit us to improve upon traditional family reconstitution methods in two respects. First, some of our ancillary information allows us to resolve otherwise ambiguous situations, for example, making clear the separate identities of two persons with identical names. Second, our supplementary information allows us to expand the “reconstitutable” portion of the population because it gives us a sharper picture of who is or is not in a community at any given time. We also use the registers of births, deaths, and marriages in a more straightforward way, simply by compiling counts of events by year. This approach yields less information than family reconstitution, but allows us to analyze

the entire population, not just the subset whose families could be reconstituted. It also makes comparisons possible, since there is a large literature based on such counts.³

Our second, quite unusual source consists of nearly annual counts of the resident population of each community based on church visitation reports. For consistency, when we are dealing with the total number of *events* reported in the registers, we called these “counts.” Information that relies on *linkage* of one of more specific events derives from the “reconstitution.” To refer to the counts of *inhabitants*, we use the term “population totals.”

We try, where possible, to compare our results to other studies, of which two are especially important. Knodel (1988)’s famous study of fourteen German villages includes one Swabian community, Öschelbronn, which lies midway between Karlsruhe and Stuttgart, about 40 km from two of our project communities (Wildberg and Ebhausen). Knodel’s source is an *Ortssippenbuch*, which is slightly different from a family reconstitution. Medick (1996)’s micro-history of Laichingen also presents results from a Swabian family reconstitution. Laichingen lies between Stuttgart and Ulm, about 20 km from our third project community, Auingen. A third study is also of some interest. Benz (1999) presents results from family reconstitutions of three Baden communities that also form part of Knodel’s study. The institutional context in the Baden communities differed in some ways from that in Württemberg, but resembled it in many ways, including subjection to the *politische Ehekonsens* until the 1860s (Matz 1980, pp. 148, 181, 231; Ehmer 1991, pp. 53-5). We refer to Knodel’s study on these Baden communities for detailed demographic results and to Benz for comparative context on illegitimacy and the marriage controls.

1. The Württemberg Communities of Wildberg, Ebhausen, and Auingen

³ Examples of that literature include our own, earlier effort (Guinnane and Ogilvie (2008)), which uses two of the three registers discussed here; Weir (1984); and Galloway (1988). The two volumes of the “Eurasia project” (Bengtsson et al. 2004 and Tsuya et al. 2010) include references to more recent studies of this type. The most famous project in this tradition is Wrigley and Schofield (1981).

Our demographic data come from the communities of Wildberg and Ebhausen in the Württemberg Black Forest, and Auingen on the Swabian Jura. Figure 1 shows their location relative to Stuttgart and Mannheim. The Duchy (after 1806 Kingdom) of Württemberg was a middle-sized state in southwest Germany – a “German territory of the second rank” (Vann 1984, p. 36). It had about half a million inhabitants in 1600, sustained serious population losses in the Thirty Years War (1618-1648), but recovered again to 320,000 by 1700, 640,000 by 1797, 1.7 million by 1849, and just above 2 million in 1900 (Boelcke 1987, pp. 93-6, 165, 215). Württemberg was repeatedly devastated by warfare, partly inflicted exogenously but also exacerbated by its institutional structure, which enabled its rulers to alternate between conspicuous consumption and destructive military ventures, as during the Thirty Years War (1618-48), the War of the Grand Alliance (1688-97), the Seven Years War (1756-63), the French Revolutionary Wars (during which Württemberg fought on both sides), the Seven Weeks War (1866), and the Franco-Prussian War (1870-1). A constant characteristic of Württemberg’s rulers was their extravagance and consequent willingness to sell monopolies and other economic “privileges” to powerful interest-groups in return for fiscal favours (Ogilvie 1999; Vann 1984; Wilson 1995).

For most of its history, Wildberg was the capital of one of Württemberg’s 45-60 districts, administering itself and 10-12 villages, one of which was Ebhausen. Although Wildberg had the legal status of a town, it was small, with a population of about 1500 in 1625, 1100 in 1650, 1300 in 1700, 1500 in 1750, 1700 in 1800, and 1800 in 1850, falling again to 1300 by 1900. Ebhausen, as a village, started out smaller but grew faster, with a population of about 200 in 1650, 350 in 1700, 650 in 1750, 1000 in 1800, and 1600 in 1850 (nearly equalling Wildberg), but then falling back to 1200 by 1900. Auingen was one of the villages of the administrative district of Münsingen, about 80 km away from Wildberg in eastern Württemberg. From 1580 up to 1634, Auingen remained a small, primarily agricultural village with a nearly stable population. The Württemberg military catastrophe of 1634 brought serious devastation, and Auingen lay totally deserted in 1645-7. Post-war recovery was slow, and Auingen did not re-attain its pre-1618 population level until c. 1760. During the eighteenth century and the early

nineteenth, Auingen more closely mirrored the slow population expansion of Wildberg than the accelerating growth shown by Ebhausen. But unlike either Wildberg or Ebhausen, Auingen maintained its population growth after c. 1850, accelerating after c. 1895 so that by 1916 it equaled Wildberg or Ebhausen in size.

Württemberg, like most of the German south, was economically undynamic between 1550 and 1914. Its agriculture was unproductive and continued to be carried out on small, fragmented holdings under the communal regulation of the three-field crop rotation system until the agrarian reforms of 1879. Württemberg industrialized late even by German standards, with factories first appearing in the 1830s but not becoming widespread until the later nineteenth century. But Württemberg did have a long history of rural crafts and export-oriented proto-industries, and in 1800 had one of the highest densities of industrial occupations per capita of any German state (Reininghaus 1990, p. 9). Alongside a general pattern of by-employed craftsmen-farmers, Württemberg had export-oriented proto-industries: the Urach linen region in the east (which included Auingen) and the Calw worsted region in the west (which included Wildberg and Ebhausen) (Medick 1996; Ogilvie 1997).

Wildberg saw the rise of export-oriented worsted production in the 1580s, and until about 1800 was the most important single centre of worsted production in Württemberg, with 120-140 independent weavers, comprising some 40 percent of its household heads. Ebhausen moved into proto-industry later, with only 25 weavers in 1670 and 50 by 1730, by which time they comprised about 37 percent of household heads. The worsted proto-industry also employed some 75 percent of the unmarried women and widows of Wildberg (and later Ebhausen) as piece-rate spinners (Ogilvie 2003). But agriculture remained important, with about 40 percent of households in Wildberg and 80 percent in Ebhausen in 1736 at least partly dependent on farming their own land (usually alongside a craft or proto-industry). This was reflected in a strongly “arable” pattern of marriage seasonality (more accentuated in Ebhausen than Wildberg), which lasted into the nineteenth century (Ogilvie 1997, pp. 253-4). The worsted proto-industry was hard hit in the 1790’s by the French Revolutionary Wars and in the first half of the nineteenth century

Wildberg and Ebhausen gradually reverted to agriculture and locally oriented crafts . Even the establishment after 1850 of a few small-scale and short-lived “factories” (wool-spinning, heckle-making, saw-milling, oil-milling, fulling, brick-making) failed to re-industrialize the local economy.⁴

In Auingen, agriculture played a much more central role. Throughout the eighteenth century, some twenty percent of grooms who stated an occupation were farmers, rising to about one-third in the mid-nineteenth century before again declining. From the mid-eighteenth onwards, Auingen experienced a dramatic rise in proto-industrial linen-weaving, and by the 1790s over half of all grooms were practising this occupation. However, by the 1850s this figure had fallen below twenty percent. Auingen’s first experience of factory employment came in 1897, when a cement factory opened in neighboring Münsingen (2 km away).

Like many other western European economies, by 1600 Württemberg was quite market-oriented (Sabean 1990; Medick 1996; Ogilvie 1997). Proto-industrial worsted- and linen-weavers exported their wares throughout Europe and imported raw materials in bulk from outside the region. Grain and other foodstuffs were widely sold to provision townspeople, proto-industrial producers, landless laborers, and the rural land-poor. Labor markets encompassed servants, day-laborers, spinners, and a whole array of miscellaneous workers. Land changed hands between kin and non-kin at a rapid rate. On rural credit markets, borrowers offered mortgages, collateral, and interest-payments to a wide array of lenders (Ogilvie et al. 2012).

On the other hand, in Württemberg all these market transactions were circumscribed by powerful non-market institutions. The Württemberg state was strong enough to entangle the territory repeatedly in military ventures, but too weak to finance them without granting costly monopolies and institutional privileges to rent-seeking interest-groups (Vann 1984; Ogilvie 1992, 1999). This entrenched the powers of two other institutions, guilds and local communities, which were much stronger here than, for instance,

⁴ For more detail on the economic history of Wildberg, Ebhausen, and the immediate region, see Ogilvie (1997, 2003); Troeltsch (1897); Mantel (1974); Klauf (1987); Königliches Statistisch-topographisches Bureau (1862).

in the Netherlands, England, or France. Guilds in Württemberg, as in many areas of central and southern Europe, did not break down after the medieval period but instead became stronger by securing state enforcement. They regulated rural as well as urban producers and existed not in just traditional crafts but also in proto-industries, shop-keeping, merchant trading, and many other secondary and tertiary occupations (Hoffmann 1905; Raiser 1978; Ogilvie 1997, 2004). Worsted textile production in proto-industrial communities such as Wildberg and Ebhausen was governed until the 1860s by strong regional weavers' guilds, which regulated prices, output quotas, techniques, labor relations, and the prices paid to suppliers such as the army of unguilded female spinners (Ogilvie 1997, 2003, 2004; Flik 1990). Worsted exporting was monopolized by a guild-like association of merchants called the Calwer Zeughandlungskompagnie which was established in 1650 and until 1797 successfully enforced its legal right to compel all local weavers to sell exclusively to its members and excluded all competitors (Troeltsch 1897; Staudenmeyer 1972; Ogilvie 1997). In a nearly identical pattern, the proto-industrial linen-weavers in Auingen were until the late eighteenth century legally obliged to sell their output to the Uracher Leinwandhandlungskompagnie, a guild-like merchant association with a state monopoly (Medick 1996; Flik 1990).

Community institutions in Württemberg offered fiscal and political support to the state in return for enforcement of their powers to regulate marriage, sexuality, migration, inheritance, citizenship, settlement, markets, residence, education, diligence, leisure, and consumption (Grube 1954; Ogilvie 1997, 2003, 2010; Sabeian 1990). Demographic behavior in particular was closely monitored and controlled. People were not allowed to marry unless they could satisfy their community council that they could support themselves, whether by inheriting land, achieving guild mastership, or obtaining some other niche in a not very rapidly growing economy (Sabeian 1990; Ogilvie 1997, 2003). Permission to marry and settle was often denied to men and women who were regarded by their communities as “economically and morally weak”, according to a set of marriage regulations that after 1800 were increasingly formalized and enforced by the state, under the rubric of the *politische Ehekonsens* (Matz 1980; Ehmer 1991; Ogilvie

1995; Schraut 1989). Together with the scarcity of legal “niches” for achieving economic independence, these marriage regulations created incentives for massive emigration from Württemberg in the eighteenth and nineteenth centuries (Bassler 1974; Hippel 1984). Guilds were not abolished in Württemberg until 1864 (Ogilvie 1997). Marriage restrictions began to liberalize only in 1862 and were abolished only with German unification in 1870 (Matz 1980; Ehmer 1991).

This was a society, therefore, in which people’s economic and demographic decisions were affected by both market and non-market factors. On the one hand, since few farmed enough land to subsist from, nearly everyone (including women) had to sell agricultural output, craft wares, proto-industrial goods, or simply their own labor to survive (Ogilvie 1997, 2003, 2004a, 2004b). On the other hand, economic and demographic decisions were regulated by powerful non-market institutions. The Württemberg state constrained economic decisions through war-induced scarcity, monetary devaluation, high taxation, and forbidding the construction of railways until the 1850s (the Wildberg-Ebhausen region did not obtain a rail connection until the 1870s, and the Auingen region not until the 1890s (Scharf and Wollny 1995)). Local communities and guilds slowed economic growth and enforced a particularly severe version of the “preventive check” on demographic behavior, by restricting access to settlement and marriage by individuals whom local elites regarded as high welfare risks or otherwise undesirable fellow-citizens. What demographic pattern emerged within this framework?

2. Sources

Our main demographic sources are Lutheran parish registers and church visitation records.⁵ After the Reformation, Württemberg became an officially Lutheran state, which it remained until 1806 when the Napoleonic territorial reorganization brought a number of Catholic territories into the new kingdom. Until then, Württemberg was religiously homogeneous and remarkably pious, aided by the efforts of a

⁵ For a more complete discussion of these demographic sources, Ogilvie et al. 2008, Appendix B.

dedicated Lutheran church administration, powerful local church courts which monitored religious observance, and community courts which typically refused settlement rights to non-Lutherans while tolerating servants and itinerant laborers from Catholic and Calvinist territories (Ehmer 1999; Fritz 1993; Holtz 1996). Even after 1806, the Lutheran territories of “Old Württemberg” remained socially distinct from the Catholic territories of “New Württemberg”. As late as 1895, only 2.4 percent of the population of Wildberg and 0.5 percent of the population of Ebhausen was non-Lutheran. Auingen remained almost exclusively Lutheran until the end of the nineteenth century; by 1905, Catholics comprised 10 percent of the village’s population.⁶

The Württemberg church began keeping registers of marriages and baptisms in 1558 and added registers of burials around 1610. Table 1 shows the start and end dates for our parish registers. Not all communities kept registers carefully from the beginning or were able to conserve them to the present day. Thus Wildberg has surviving marriage registers from 1558 on, burials from 1615 on, but baptisms only from 1646 on because the first register was destroyed in the Thirty Years War. Ebhausen recorded marriages inconsistently from 1559 to 1561 and consistently from 1604 on, burials from 1571 on, and baptisms from 1559 on. Auingen has all three registers from the late sixteenth century, but shows definitive evidence of consistent recording-keeping only from the mid-seventeenth century. Table 2 provides details on periods when coverage may not have been complete. Although any registration system can be evaded given sufficient motivation, local communities and churches exercised sufficiently close surveillance that the costs of evasion were high (Ogilvie 1997; Sabean 1990), giving good grounds for confidence that the data extracted from these sources reflect the actual demographic situation.

3. Population Size

⁶ See Ogilvie et al. 2008, p.65. Catholics in Auingen remained under the pastoral care of the priest in nearby Magolsheim.

Figure 2 presents the population for each community, based on the church visitation reports.⁷ The economic history described above is clearly reflected in the demographic record. Initially Wildberg was by far the largest of the three communities, but experienced only slight growth across the eighteenth century and then some decline during the nineteenth. Ebhausen was at first tiny in comparison, but its strong eighteenth-century growth caused it eventually to surpass Wildberg. Ebhausen shared Wildberg's population decline during the second half of the nineteenth century and by 1914 the two communities were of essentially equal size. Auingen began as and remained the smallest of the three communities, but steady growth during the eighteenth and nineteenth century distinguishes it from the other two. By the end of the period, the three communities were approaching nearly equal size.⁸

4. Counts and Crude Rates: Nuptiality, Fertility, and Mortality

Counts of demographic events are interesting for two reasons. First, they pertain to the entire population, not just those whose families can be reconstituted. Second, with our ancillary sources providing population counts, we can use the event-counts to derive crude demographic rates that can be compared with findings for other localities.

4.1. Counts

⁷ These reports are not quite annual; for the few missing years, the graph uses a linear interpolation. For Ebhausen we also have the populations of "*Filialen*," smaller, outlying communities that were sub-parishes of the village church. We do not include them in Figure 2 and they are not included in our family reconstitution.

⁸ For Wildberg we have two distinct estimates for 1818 (1593 and 1594 persons) as well as for 1821 (1560 and 1786 persons). We use the average of the two totals, although the differences are too small to affect the results reported here.

Figure 3 shows the total number of marriages annually in each community. To reduce extraneous fluctuation, we present the figures as centered seven-year moving averages.⁹ Marriages in Wildberg and Ebhausen were markedly correlated across years, with the small peaks and valleys usually appearing at the same time. This pattern reflects, in part, reactions to common shocks in their local economies which were similar since they were located only 11 km apart in the same administrative district. In Auingen the shocks appear to have been different, not surprisingly given its location 80 km away on the other side of the country. Auingen experienced the large early-nineteenth-century upswing in marriages, for instance, over a decade later than the other two communities. Towards the end of the nineteenth century there were marriage “booms” in Wildberg and Ebhausen, also observable to a lesser extent in Auingen. These booms, we argue below, reflect the abolition of the *politische Ehekonsens* in 1870.

Figure 4 reports the number of deaths in each community, again presented as centered seven-year moving averages. We plot deaths in Wildberg against a different vertical axis, to allow for its large mortality spikes in the seventeenth century. Württemberg was part of a central European zone known for especially high infant and child mortality, whose important role in our communities is analyzed below. Figure 4 illustrates a second feature of mortality in this society: the frequent occurrence of short, sharp spikes in deaths. Wildberg’s two mortality crises in the seventeenth century reflect war and invasion; the other, less dramatic fluctuations show the influence of crop failures and other economic crises, as well as episodes of infectious disease (Guinnane and Ogilvie 2008; Ogilvie et al. 2009, pp. 25-36).

Figure 5 presents the same information for births, again as centred seven-year moving averages.¹⁰ Wildberg differs from the other two communities in manifesting relatively stable annual birth numbers from c. 1700 straight through to the massive peak just after 1870. Ebhausen and Auingen, by contrast,

⁹ That is, the value reported for 1750 is the sum of the counts for 1747-1753, divided by seven. Figure 3 includes all marriages. Below we discuss differences between first and higher-order marriages. Guinnane and Ogilvie (2008) report econometric analysis of marriages, deaths and births as reactions to economic “shocks,” using the techniques employed by Weir (1984).

¹⁰ Figure 5 includes both illegitimate births and stillbirths. The dividing line between stillbirths and live births is not always clear-cut, but the range of error is small relative to the levels in Figure 5. We discuss the issue in more detail in section 7 below.

show continually growing annual birth numbers from the mid-seventeenth century onwards, though they diverge in the nineteenth century, when Ebhausen experienced massive fluctuations while Auingen saw annual birth totals growing continuously up to 1914. The smaller amplitude of movements in births in Auingen may reflect its less dramatic overall changes in population. The upswing in births in the 1870s, most visible in Wildberg and Ebhausen but also discernible on a smaller scale in Auingen, coincides with the abolition of the *Ehekonsens* in 1870.¹¹

4.2. Crude Rates

Most family reconstitution studies lack any direct count of the number of people living in a community and thus “under observation” at a given time. Without firm estimates of the population at risk, it is not possible to compute true demographic rates, making it difficult to compare results across communities. For example, an increase in the number of deaths may reflect *either* an increase in the death rate *or* a shift in the population’s age-structure towards those with higher age-specific death rates. The existing literature either works around this lacuna or attempts to estimate population counts indirectly, for instance by using methods of inverse- and back-projection.¹²

Because we have independent population counts from church visitations, we can estimate crude demographic rates directly. We can combine the population counts in Figure 2 with the counts of events reported in Figures 3-5 to estimate the number of marriages, deaths, and births per thousand inhabitants in a year. Figures 6-8 present crude rates for marriages, deaths, and births, aggregating by quarter-century to smooth out some of the fluctuations evident in the earlier graphs.¹³ The crude rates are similar across the three communities, and all three are in line with studies of other communities from the same period,

¹¹ We discuss legitimacy and illegitimacy below.

¹² See Wrigley and Schofield (1981). Wrigley et al. (1997) undertakes this with family reconstitutions.

¹³ The year given on the horizontal axis in each graph is the beginning-year of the quarter-century in question: thus “1700” indicates the quarter-century 1700-1725. Exceptionally, “1875” indicates the period 1875-1914

including those outside Germany (see, for example, Wrigley et al. 1997, Appendix 9). Birth rates usually exceed death rates to a degree indicating continuous emigration. This is consistent with the view that the institutional controls discussed above denied many young people an adult's place in their community of birth. Comparing Figure 7 with Figure 8 shows greater inter-community variation in birth rates than in death rates. This difference hints at differences we explore below: most of the inter-community variation in crude death rates apparently reflects differences in the age-structure of these communities, but the differences in birth rates reflect both age-structure and differences in nuptiality patterns, to which we now turn.

5. Nuptiality

Marriage marks an important transition in the lives of the people we study, and is a central aspect of the distinctive demographic regime that historians associate with western Europe. Most studies find that until the nineteenth century, nuptiality was the primary regulator of fertility in European populations. In a population where illegitimacy was rare, and there was little effort to control fertility within marriage, the number of children a woman bore was a function of whether and when she married. As we shall see, our communities had a growing proportion of illegitimate births from the late eighteenth century on, but even then, the fertility of these "outsider" women was much lower than that of their married sisters. For the community as a whole, the fertility rate largely reflected the proportion of women who were married, and their current ages.

5.1. The European Marriage Pattern

In two influential studies Hajnal (1965, 1982) pointed out that young adults in western Europe married relatively late in life and substantial proportions never married at all. If anything, Hajnal's

original article understated the robustness of this pattern; even places such as pre-Famine Ireland, where observers had long claimed to see early and universal marriage, turn out to have corresponded to Hajnal's description.¹⁴ In his compilation of more than one hundred family reconstitution studies for England, France, Belgium, Germany and Scandinavia in the eighteenth and early nineteenth centuries, Flinn (1982, Appendix Table 7) finds mean ages at first marriage for women of about 25, with few communities showing a mean value lower than 24. The proportion of adults in western Europe who remained unmarried throughout their lives was high, especially in comparison to east Asia, where permanent celibacy for women was rare. Feng et al. (2010, Figure 11.1), for example, report that in the Chinese community of Liaodong, virtually no women experienced lifelong celibacy in the period 1789-1840. Generally about 10 percent lifetime celibacy for both men and women seems to have been "normal" for the European zone Hajnal had in mind.

The regulation of economic and demographic life that characterized Württemberg provides a different understanding of Hajnal's views of western Europe. Hajnal (and most demographic historians) view the western European marriage pattern as resulting from informal social norms according to which couples were expected not to marry unless they could set up a separate household and support themselves independently. Some couples might marry in contravention such social norms, and neither their community nor any other institutions had the ability to prevent such marriages. The central European *politische Ehekonsens*, by contrast, gave these norms legal teeth: the community could do more than disapprove. To the extent that the community was more conservative than the individuals were themselves, it effectively separated young adults into those privileged to marry and those for whom marriage would require leaving the community. The *Ehekonsens* divided people into insiders and outsiders.¹⁵

¹⁴ Guinnane (1997) focuses on post-Famine Ireland, but includes comparative discussion for much of Europe.

¹⁵ One way to think about the *politische Ehekonsens* is to recall Malthus' objections to "early and improvident marriages" and the English Poor Laws' supposed role in fostering such marriages. Malthus objected to some marriages and many of his contemporaries doubtless felt the same way. But they had no legal right to forbid them, a right possessed and exercised by the Swabian communities we study here. On the legal framework and concrete

Two features of family reconstitution studies bear on the results that follow, and need to be kept firmly in mind. First, many studies of nuptiality (such as Ehmer 1991 or Guinnane 1997) rely on censuses or similar household listings that report the marital status of everyone in a community. Family reconstitution, on the other hand, only reports events, and thus does not typically generate measures directly comparable to those derived from censuses. We cannot, for example, estimate the proportion of adults in a given age group who had never married, because we cannot reliably construct the age-structure of the total population of a community at any given point in time.

Second, family reconstitution studies can include only those who remain in the community and take their demographic decisions there. But the operation of the *politische Ehekonsens* implies a strong link between marital status and residence in the community. Those denied permission to marry might well leave the community precisely for that reason. Since we cannot follow the lives of those who leave our communities, we cannot reliably determine the proportions never-married in any given birth cohort. By contrast, in a community lacking such strong control over marriage, one would not necessarily expect a strong correlation between marriage decisions and out-migration decisions.

5.2. Age at Marriage

Tables 3-5 report age at marriage in each community, according to the marital status of the bride and groom.¹⁶ We report both measures of central tendency (means and medians) and measures of the variation (the upper and lower quartile). For some individual cells, the number of individuals is too small

implementation of the *politische Ehekonsens* in Württemberg, see Matz 1980, esp. 44-5, 120-1, 181, 191; Ehmer 1991, esp. 53-5; Ogilvie (1997), 61-3; Ogilvie (2003), 51-4.

¹⁶ Tables 3-5 include a bride or groom if she *or* he has a valid birthdate; that is, the number of events recorded from a given marriage need not be equal. For the seventeenth century, especially in Ebhausen, the register did not record marital status at marriage for some brides and grooms. Based on the conventions governing how individuals were identified in written documents in this society, however, brides of unknown marital status can be assumed to be unmarried in almost all cases, while grooms of unknown marital status can be assumed to be widowers. The ages at marriage reported in our tables are not sensitive to variations in treatment of this problem. If we simply exclude all brides and grooms of unknown marital status, the sample becomes smaller without appreciable changes in the mean or median age at marriage reported in the tables.

for firm comparisons, especially with the wide distributions implied by our measures. But a measure such as the median is robust to sample-size issues.

Ages at first marriage in our communities fall within the range usually found in Hajnal's western European zone, but on the high end of that range, especially for women.¹⁷ Age at first marriage also rose considerably in the early nineteenth century in all three communities, contrary to the trend in England over the same period. Not surprisingly, widows and widowers were older at marriage than single people. This reflects two forces. The first is mechanical: to remarry requires a first marriage and widowhood. The second reflects the *politische Ehekonsens*: marriage reflected a privileged status, one that made a widow or widower attractive in addition to the other attributes correlated with age. The difference increases over time, especially in the nineteenth century; in Wildberg, for example, we even find some widows remarrying in their forties. The desire and ability to remarry at that age suggests that at least these unions were not motivated by a desire to have more children.

Tables 6-8 report age differences between spouses, which are also within the range usually reported in European family reconstitution studies. However, one feature of these results warrants emphasis: the relatively narrow gap in ages, especially in first marriages for both partners. Often in populations with high marriage ages, males are significantly older than females at first marriage. The difference is usually interpreted as reflecting the relatively greater impact of age on female than on male fertility: a man of thirty-five can still father a large brood, while a woman of thirty-five probably cannot. In our communities, men who married at all tended to do so at ages not very different from their spouses. This narrow age gap may be another indicator of the way the separation between insiders and outsiders affected marriage. In the contexts Hajnal was contemplating, a man could become a more attractive mate by waiting to marry, and in the meantime accumulating assets and professional qualifications. For a woman, youth was an important attribute, meaning that in contexts where many persons never married,

¹⁷ Flinn (1981, Appendix 7) reports only a handful of studies with a female mean age at first marriage outside the range observed in our three communities. He does not report male age at marriage. Medick (1996)'s Laichingen reconstitution (Table 4.3) reports a similar pattern, with female ages at first marriage reaching a mean of 27.4 in 1850-74.

we would not be surprised to see husbands much older than their wives. The *politische Ehekonsens*, by contrast, reflected community decisions about attributes that would not change as a man became older. He was, for example, either in line for a guild mastership, or not.

5.3. Lifetime Celibacy Rates

Family reconstitution studies typically use reported marital status at death for persons over 50 as a proxy for lifetime celibacy rates. Table 9 reports proportions ever-married for people who died age 50 or older. These estimates must be qualified in two ways. First, because the registers' coverage ends in 1914, we lack death dates (and hence marital status at death) for many people born in the later nineteenth century; these individuals do not appear in the table. Second, our figures may under-represent immigrants into our communities since accurate information about their age may not have been available to the clergyman recording their burials.

The table shows considerable variation across our communities, even at the same date, but some regularities stand out. Proportions ever-married for men invariably exceed those for women. This difference does not imply that men were more likely to marry than women were, but rather that fewer men than women who failed to marry remained in the community until after age 50. Especially in the later eighteenth century and throughout most of the nineteenth, men who could not marry left the community, while more women who could not marry remained. This pattern reflects underlying differences between the sexes in the attractiveness of remaining as a single person in our communities relative to opportunities available elsewhere (Ogilvie 2003). These gender differences become particularly striking in the late eighteenth century, implying a growing number of never-married women remaining in our communities. From the early to mid eighteenth century onwards, the proportion of women never married in Wildberg places that community at the extreme of the western European marriage pattern, along with Ireland, other regions of the European "fringe," and those wide swathes of

central Europe subject to institutional controls on marriage (Ehmer 1991; Ogilvie 1995; Mantl 1997, 1999; Veichtlbauer et al. 2006).

6. Mortality

Württemberg was part of a central European zone where mortality remained high well into the nineteenth century. Infant and child mortality was, relative to adult mortality, especially high; in fact, Germany underlies the “East” family of model life tables in the Coale-Demeny system. Knodel (1988, Table 3.1) reports a combined infant mortality rate of 30 percent for Öschelbronn, the Württemberg community in his sample.¹⁸ Throughout the eighteenth and nineteenth centuries, some 38-40 percent of all newborns in Öschelbronn did not see their fifth birthday. Medick (1996, Table 4.16) reports even higher rates for Laichingen, where in the 1670s about one-quarter of all children died before their first birthday, rising to 48.6 percent by the mid-nineteenth century.¹⁹ Auingen, Ebhausen, and Wildberg shared this experience, with extremely high mortality for infants and children.

Mortality studies based on family reconstitutions typically focus on infant and child mortality.²⁰ As in other contexts, proper estimation of demographic rates (in this case, death-rates) requires that we know when individuals are under observation, and our sources allow us to do that with tolerable certainty only for children. The problem lies in the lack of a recorded death date for some individuals. A missing death date almost certainly indicates that the person moved away from the community and died elsewhere, but we typically cannot know when they died. For children, however, we can use recorded

¹⁸ The figure cited in the text includes stillbirths and covers the entire period of Knodel’s study, roughly the eighteenth, nineteenth, and early twentieth centuries. Öschelbronn experienced a sharp fall in infant and child mortality in the late nineteenth century, similar to the decline we document for our communities below.

¹⁹ Medick’s estimates apparently include illegitimate children, and he uses a different approach to dealing with children whose date of death is not known, so his estimates are not directly comparable to ours.

²⁰ Wrigley *et al.* estimate adult mortality from their family reconstitutions. The challenge for this type of analysis is to estimate the numbers and ages of adults at risk of death, which in a mobile population requires possibly heroic assumptions. A second approach is to rely on model life tables to infer adult mortality from the mortality levels estimated for children. We prefer this approach, like Knodel (1988), and return to it at the end of this section.

information for other family members to infer the family's presence or absence in the community, since we can reasonably assume that young children do not migrate without their parents.

In calculating mortality levels we base our analysis on two types of children: those for whom we have death dates, and those lacking death dates but for whom we have the death date of a parent after the child would have turned five. This approach may impart some bias. The longer the parents lived, the more time they had to move away, meaning we are more likely to include a child whose parents had relatively short lives. If parental and child mortality risks are correlated, which they must be to some extent, then we are selecting for children who faced higher mortality risks. The risk of bias is slight, however, as the populations of our communities are relatively immobile. In Auingen, for example, only 1,792 of 4,692 births (about 38 percent) could not be linked to a death date. Of these, 1058 were children born after 1850, when migration to and from all of our communities increased.²¹ A greater source of bias may be the fact that, as with all family reconstitution studies, we can only analyze births linked to parents; our results, like all others, apply to the reconstitutable portion of the population.²²

6.1. Stillbirths

We begin with the tricky issue of stillbirths. In principle, all mortality estimates pertain to individuals born alive; fetuses that die *in utero* are excluded from the analysis. The problem is to infer which children were born alive from notations in the baptism registers. Even modern statistical agencies face difficulty in collecting consistent data on stillbirths, and here all we have to go on are handwritten descriptions in our primary sources. Table 10 illustrates the definitional issue for Wildberg alone. The “narrow” definition of a stillbirth in the table relies on the notations in the primary source (discussed in

²¹ In Ebhausen we lack death dates for 2225 of 9779 (or 23 percent) of the children linked to a birth. Of those, 686 were born after 1850. In Wildberg we have 11,377 births, of which 34 percent are not linked to a death. Of these 3942 births missing a death date, 1202 were born after 1850.

²² One might be tempted to infer that a child remained in the community using information on the birth or death of *siblings*. We deliberately do not use such information, as it would definitely be selecting on individuals whose parents had more births and perhaps higher rates of infant mortality.

greater detail in Appendix A below), and may therefore underestimate stillbirths, because of the concern for soul of a child who was not baptized. The “broad” definition assumes that a child was stillborn if its birth and death dates were listed as the same, and may therefore overestimate stillbirths as it includes infants who were born alive but lived for up to 24 hours.

The proportion of stillbirths increased across the entire period under analysis up to the end of the nineteenth century, when it began to decline. The trend was broadly similar across all three communities, suggesting that changes over time do not reflect idiosyncrasies of recording in any one place. The decline in the late nineteenth century probably reflects better conditions for expectant mothers as well as improvements in the delivery of babies.

The increase in stillbirths in the period before the late nineteenth century is more complicated to explain. It could reflect reporting practices, although that seems unlikely given that both narrow and broad measures follow roughly the same trend. It also seems unlikely that reporting practices would fluctuate in precisely the same way across three communities in different parts of the country. The increase might reflect changes in the experience of pregnancy: perhaps women who would have suffered a miscarriage in the early seventeenth century were able to bring to term more fragile fetuses in the early nineteenth.²³ Finally, the rising rate of stillbirths may reflect changes in married women’s work: although Ogilvie (2003, pp. 149-52, 194-200) found that married women in Wildberg and Ebhausen already engaged in heavy manual labor in the 1650-1800 period, Sabeau (1990, pp. 130-1, 138, 176-8) has argued that after c. 1800 agricultural changes in Württemberg villages made married women’s work even more valuable. Increasing economic pressures on married women between the mid-seventeenth and the mid-nineteenth century would help explain rising proportions of stillbirths, as well as the rising rates of infant and child mortality discussed below.

²³ Illegitimate children were approximately twice as likely as legitimate ones to be marked as stillborn in all three communities. This difference probably reflects both conditions of pregnancy (since unmarried pregnant women were even more likely to have to keep working late in pregnancy than married ones) and the conditions under which such children were born (since unmarried pregnant women were more likely to be poor and “outsiders” to the mainstream community).

6.2. Infant and Child Mortality

One characteristic of the high mortality suffered by our Württemberg populations is the concentration of deaths very early in life, not just in infancy, but *early* in infancy. Table 11 reports two variants on a common measure that captures mortality experience early in life. *For those who died before their first birthday*, the table reports the proportions who died in the first week and in the first month of life respectively. Infant mortality in all three communities was concentrated very early in infancy, with about one-quarter of all infant deaths occurring in the first week of life, and one-half occurring within a month. This age-pattern hints at the reasons underlying such high mortality. In populations that practice little breastfeeding, neonates are especially susceptible to gastro-intestinal infections brought about by consumption of breast milk substitutes..²⁴

Table 12 reports two standard measures of infant and child mortality, excluding births with a stillbirth annotation. The very low estimates for the seventeenth century probably reflect missing links in the reconstitution at a period when registration was just starting up and was also disrupted by the Thirty Years War. From the mid to late seventeenth century onwards, the estimates confirm the earlier indications of extremely high mortality, with up to half of all children dying before their fifth birthdays. Although mortality rates eventually declined in the final period covered (1875-1914), they actually increased in the mid-nineteenth century, especially in Auingen.

Table 13 delves into another feature of infant mortality: its seasonality. Mortality was much worse for children born at some times of the year than in others.²⁵ These strong seasonal effects highlight the underlying causes of death for infants in these populations: the risk of exposure to gastro-intestinal

²⁴ Table 11 excludes stillbirths. In the next section we report very high fertility rates early in marriage, another indicator of low breastfeeding rates.

²⁵ The table reports only the proportion of children born in a given month who died in the first month of life. The basic patterns shown in Table 12 are similar in the proportion that died within the first week or the first year of life. In discussing seasonality we focus on mortality up to age one month in order to reduce ambiguity concerning which “season” the child experiences.

disease, especially for children who were not fully breastfed. The late summer and early autumn were usually the worst. Auingen, the most agricultural of the communities, had the most pronounced seasonality in infant mortality. This difference between Auingen and the other two communities, whose occupational structure was more proto-industrial, may indicate an interaction between environmental and behavioral factors, with women finding it harder to breastfeed during the late summer and early autumn when agricultural but not proto-industrial labor demands were at their peak. Knodel (1988, Figure 3.7) reports similar seasonal patterns for Öschelbronn to those we observe in Auingen, and suggests that it reflects variations in breastfeeding intensity across the year. Mothers who were busier during the harvest season might begin to introduce substitutes, exposing their babies to greater risk of infection.

What do our estimates of mortality patterns imply more generally? Consider first their implications for family-building. These very high mortality levels suggest at least the possibility of infant and child mortality that is endogenous in the economic sense of the term. That is, mortality may have been high because many parents did not make investments in their children's survival, even though such investments were technically feasible.²⁶ This possibility implies that parents were, at some level, using infant and child mortality instead of contraception to reduce their brood's size, or at the very least that breastfeeding practices reflected the opportunity cost of mothers' time. We cannot draw firm inferences on this point without more detailed analysis of fertility and mortality. To the extent that these mortality levels are *exogenous* in the economic sense of the term, they imply considerable difference between fertility and the number of children actually raised. A five-year mortality rate of 40 percent implies that even in a population with a Total Fertility Rate (TFR) of ten, parents see only six children enter late childhood.

What do these mortality estimates imply for mortality later in the life-cycle? At a later stage of research, we will combine our population listings with the family reconstitution to estimate adult mortality parameters directly. But in the absence of such unusual data sources, we can estimate adult

²⁶ The historical demographic literature uses the term "endogenously" differently. See Bourgeois-Pichat (1951).

mortality levels by combining data on infant and child mortality with model life tables. Knodel (1988, pp. 53-60) takes this exercise seriously, although he begins by noting that the Coale-Demeny life tables do not fit mortality in his populations very well. We share that view for our communities.²⁷ For this illustration, we limit ourselves to females and focus on the “East” life tables. An infant mortality rate of .360, which is on the high side for our three communities, corresponds to Coale-Demeny level 3, with an expectation of life at birth of 25 years, and an expectation of life at age ten of 41 years. An infant mortality rate of .216, on the low side for our communities, corresponds to Coale-Demeny level 9, which implies an expectation of life at birth of 40, and at age ten of 52 years.²⁸ For comparison, Knodel (1988, table 3.3) concludes that mortality in his Württemberg village of Öschelbronn was most consistent with an expectation of life at birth of 32.6 years and at age 10 of 37.8 years. High though the mortality in our villages was, therefore, it was not as high as that estimated for other Württemberg communities. Overall, these mortality patterns imply that most newborns in Württemberg before the late nineteenth century faced very poor chances of ever reaching late childhood. But if the model life-table relationships discussed above are even tolerably accurate, any child who survived the “fatal years” could expect to live into late adulthood.

7. Marital Fertility

We now turn to marital fertility. Württemberg has enjoyed little of the sustained attention paid to the historical demography of England, France, and other European countries, so our three reconstitutions mark a considerable advance on what is known about marital fertility in this area. Two earlier studies offer the chance for comparison. Knodel (1988)’s fourteen German communities include the Württemberg village of Öschelbronn, and Medick (1996) reconstituted the families of the Württemberg

²⁷ A simple summary is that in our communities infant mortality is higher relative to child mortality than the “East” model life tables imply. Thus any estimate of adult mortality will depend on whether it is based on infant or on child mortality estimates.

²⁸ Our estimates of mortality to age five imply somewhat less severe mortality, ranging between levels 4 and 10.

village of Laichingen. Both studies faced the problem that the most common indicators of marital fertility use information inefficiently: the age-specific marital fertility rate, for example, reduces the fertility experience of all women in a five-year age cohort to a single number. For this reason, Knodel (1988) reports many of his results for all fourteen German communities combined, even though there was very considerable demographic variation across villages, including in key indicators such as infant mortality and marital fertility. Because we are interested in the social and economic underpinnings of marital fertility, we report results for our communities separately, even if in some instances the number of observations in a given cell is smaller than one would like. This we view as a limitation of the measure, not of our source; the next stage in our project relies on statistical approaches that make more efficient use of family reconstitution data.

We focus on the 150 years after 1750, dividing our couples into the marriage cohorts of 1750-99, 1800-49, and 1850-99. We adopt the same selection criterion as Knodel and Medick: our results pertain to first marriages that lasted until the wife was at least 45 years old. We also exclude prenuptial births. Figure 9 reports age-specific marital fertility rates for our three communities.²⁹ All three communities fit squarely within the fertility patterns suggested by the studies of Öschelbronn and Laichingen, with high natural fertility and little or no fertility control until the end of our period. In fact, the estimates reported here put considerable interpretive flesh on the results Knodel and Medick reported. Knodel did not single out either Öschelbronn or the underlying institutional and economic context of his communities, and thus did not underscore the connection between the unusually high marital fertility in Öschelbronn and any features of its economy or institutions. Medick focused on proto-industrialization and the way it worked in Laichingen, but his demographic results comprise a small part of his study, he was not in a position to compare his findings with other places, and he did not consider the role of the social or institutional framework in his demographic results. By analyzing three Württemberg communities that exhibit broadly similar fertility patterns, we are now in a position to conclude that this is what marital fertility looked like

²⁹ Following Knodel and others, if the first birth interval is shorter than nine months, we “back date” the marriage so that the first interval has the same length as the mean for first births that did not reflect bridal pregnancy.

in Württemberg, whether in a proto-industrial or an agricultural context, and to explore how it was related to the institutional context discussed above.

The results for Auingen illustrate the limitations of measures such as the age-specific fertility rate, and implicitly, the reasons that Knodel often combined all fourteen communities in reporting such measures. The Auingen figures exhibit less fertility decline with age than is present in the Coale-Trussel natural fertility schedule. This is true even abstracting from the estimates for the period 1850-99, where the fertility rates at ages 40-44 and 45-49 are based on fewer than 50 women. While conclusions must be drawn with caution at this point in the analysis, Auingen women appear to have continued to bear children after the age of 30 at a rate not typical of other European populations. The underlying reasons for this difference, which may relate either to the proximate determinants of fertility or to volitional behaviour, we reserve for future research.³⁰

The Coale-Trussel (1978) parameters “M” and “m” provide a convenient summary of a fertility schedule, even if later studies have highlighted some of the method’s drawbacks. The Coale-Trussel model fits the parameters “M” and “m” such that

$$f(a)/n(a) = Me^{mv(a)}$$

where $f(a)$ is the fertility schedule for the “target” population and $n(a)$ is a natural fertility standard derived from populations believed not to be practicing fertility control. The estimated parameter “M” can be thought of as scaling the level of natural fertility in the target population. The $v(a)$ schedule reflects deviations from the natural fertility schedule brought about by fertility control.³¹

Knodel (1988)’s estimates of “M” for the Württemberg village of Öschelbronn range between 1.01 and 1.18 (as shown by his Table 10.4) and his estimates of “m” are consistent with a natural-fertility

³⁰ The estimates of age-specific fertility in Figure 9 and Table 13 exclude women who contribute less than one year of observation to a cell. This avoids the situation where, for example, a woman has a birth just before turning 25, thus producing a rate that is correct but misleadingly high.

³¹ Since “m” measures the reduction of fertility at older ages, it is best viewed as an indicator of “stopping.” Earlier studies estimated “M” and “m” by taking logs and fitting a straight line. The estimates we report are based on the preferred approach of estimating the model in “levels” by nonlinear least squares. As a rule of thumb most demographers consider a Coale-Trussell “m” greater than 0.2 as evidence of parity-dependent fertility control.

regime until the end of the nineteenth century (Table 11.1). We also computed these two parameters for the Württemberg village of Laichingen from the data in Medick (1996, Table 4.1). Here, “M” was about 1.3 for most of the eighteenth and nineteenth centuries; natural fertility in Laichingen, therefore, was initially some thirty percent higher than in the natural fertility standard. Laichingen’s value of “m”, by contrast, implies significant fertility control starting in the late eighteenth century. The age-specific fertility rates for both Öschelbroon and Laichingen are indeed very high: in Laichingen, married women in their twenties had between 500 and 600 births per thousand woman-years of exposure throughout the entire period analyzed (1658-1884), and fertility continued to be high over the age of 40, with 208 births per thousand woman-years for Laichingen women aged 40-44 in 1825-49.

Table 14 reports “M” and “m” for our three communities, summarizing the information in Figure 9. Most of these estimates are reassuringly similar to those found for the two previously studied Württemberg communities. Values of “M” are one or greater, indicating a high level of natural fertility. The estimated “m” values suggest little or no fertility control in Ebhausen or Wildberg. The negative values of “m” reported for Auingen require some discussion. The Coale-Trussel model does not rule out this possibility: negative values of “m” mean that fertility falls more slowly with age than in the natural fertility standard, which is already apparent in Figure 9. But because this result is unusual we investigated it more deeply. Table 14 reports a second set of “M” values, estimated simply by taking the ratio of target to natural fertility in the age group 20-24. For Ebhausen and Wildberg, the two estimates of “M” are similar, while in Auingen the simpler approach yields much higher levels of “M”. This difference implies that the Coale-Trussel model has trouble fitting the idiosyncratic fertility profiles of Auingen. We also re-estimated the model by fixing “M” at the value implied by the simple ratio in Table 14, and estimating only “m”. These “m” estimates were still negative, but had much smaller absolute values than those in Figure 9.³²

³² We also re-estimated “M” and “m” with weights for the number of woman-years of exposure in each cell. This did not yield appreciably different results.

Table 15 reports two other simple measures of fertility control. The mean age at last birth is a measure of “stopping” or the truncation of fertility. The ratio of total fertility at older ages to all ages (here, ages 30+ to 20+) is a more general way to assess the concentration of fertility at younger ages. In the natural fertility standard this ratio has a value of .504. Perhaps not surprisingly, these measures yield contradictory results for Auingen, but in Ebhausen and Wildberg both measures suggest some limitation of fertility in the nineteenth century. In summary, Tables 14 and 15, together with Figure 9, show that marital fertility was extremely high in our three communities, and that there is some indication of modest reductions in fertility in the later nineteenth century. Our results demonstrate that the earlier findings reported by Knodel and Medick were not simply flukes, but indications of a distinct demographic regime generated by the socioeconomic and institutional framework in Württemberg.

But why was marital fertility so high in this society? Knodel’s investigation of the proximate determinants of fertility implies that high levels of natural fertility in pre-transition southern Germany reflected a combination of low breastfeeding and high fecundability. Tables 11 and 12 imply there was little breastfeeding in our three communities: infant mortality was high, and many of those infant deaths occurred in the first month of life.

Our reconstitutions also imply high fecundability. Fecundability refers to the monthly probability that a woman becomes pregnant if not using birth control, and thus summarizes the risk of pregnancy in a natural-fertility population. There are several ways of estimating fecundability. One simple approach uses Knodel and Wilson’s adaption of Bongaarts’ model. Since in the absence of prenuptial births, women are not breastfeeding in the first birth interval, the timing of births in that interval yields an estimate of fecundability. Knodel (1988, Table 10.6) reports the proportion of all first births that occur in the tenth, eleventh, and twelfth month of marriage (omitting prenuptial pregnancies and women with premarital births). We replicated his approach for our three communities, obtaining similar estimates and thus comparable levels of fecundability. There is thus no puzzle about how women in our Württemberg communities bore so many children.

These findings provide an important enhancement to our understanding of this “insider-outsider” demographic regime. This was a society in which access to marriage, and thus to marital fertility, was rationed. “Outsiders” did not marry at all, and even “insiders” married very late. But once a woman became an “insider” by gaining access to one of the rationed marriage niches, she enjoyed an unusually high level of marital fertility which, at least in some cases, endured to a relatively advanced age. This “central European” version of Hajnal’s European Marriage Pattern thus differed from the English version in which a larger proportion of people gained access to marriage, but then had relatively low fertility within marriage. In the central European version, by contrast, “insiders” had extraordinarily high fertility while “outsiders” had extraordinarily low fertility. The net effect on population growth may have been similar, but the socioeconomic causes and consequences were very different.

8. The Repeal of the *politische Ehekonsens*

The system of economic, social, and demographic controls on access to marriage (and thus to marital fertility) in Württemberg was abolished in several steps in the second half of the nineteenth century. Württemberg abolished guilds, one of the institutional underpinnings of the marriage controls, in 1864. Other changes, including the right to migrate freely within Germany, only came with the Reich. The *politische Ehekonsens* was repealed in two stages. Württemberg relaxed the marriage controls starting in 1862, but this resulted in a long struggle between proponents and opponents that ended with the death of King Wilhelm I in 1864 (Matz (1984, Chapter 4). The new King Karl I appointed liberal ministers who started the legislative process towards reform, and also used their influence to weaken the operation of the *Ehekonsens* while it still prevailed. From 1862 to 1871 the *politische Ehekonsens* was still the law, but a law whose hitherto severe local implementation was increasingly weakened by oversight at the national level. When Württemberg joined the Reich, it had harmonized its law with the

pre-existing law of the North German confederation, and the *politische Ehekonsens* in Württemberg came to a complete end on January 1, 1871 (Matz 1984, pp. 139-40).

We have already seen the effects of the abolition on demographic behavior in our communities. It may therefore be surprising to learn that there is some dispute in the historiography over whether the rules implicit in the *Ehekonsens* were ever applied, at least with enough consistency and force to create real impediments to marriage. Some of the disagreement arises from the widely held view, perhaps most forcefully put forward by Jürgen Schlumbohm, that pre-modern states, particularly in German-speaking central Europe, did not enforce most of their laws, ordinary people did not comply with them, and hence the legal system did not affect people's choices. Instead, Schlumbohm argues, we should adopt Michel Foucault's view that medieval and early modern legal systems were not functional, but rather served a purely symbolic purpose: they amounted to the assertion of sovereignty by a "theatre state".³³ In the specific context of the *Ehekonsens*, Knodel (1967, p. 293) shows that the German marriage restrictions affected marriage and illegitimacy rates. This is different from the question of whether they impeded population expansion: because the *Ehekonsens* apparently increased illegitimate fertility, it had less effect on population overall. Matz (1980, p. 233) expresses doubt about the effectiveness of the marriage laws on the grounds that only about 6 percent of the marriage applications he analyzed were rejected. Schraut (1989, p. 137) interprets evidence from the Württemberg city of Esslingen as "an expression of the low degree of effectiveness of the legal obstacles to marriage." Ehmer (1991, p. 74) speculates that the marriage restrictions may have been more effective as an instrument of social control against the lower strata than as a tool for influencing actual demographic behavior.

Some of the disagreement reflects the source material available and the fact that the demographic implications of the *Ehekonsens* were complex. People denied the right to marry might simply leave the community or even the entire country; certainly the nineteenth-century period which saw the highpoint of the marriage restrictions also saw epidemic emigration from Württemberg to America and eastern Europe.

³³ Schlumbohm (1997), 649-50, 660-1; referring to Foucault (1975).

For this reason, the restrictions on marriage might not have much impact on observable celibacy rates. Furthermore, while it seems likely that the *Ehekonsens* would lead to later first marriages, that is not necessarily so: people deemed unfit to marry would not necessarily become more fit just by waiting, and those forced by the regulation to wait might instead just emigrate.

Efforts to determine the effects of the *politische Ehekonsens* empirically have remained inconclusive. The challenge can be seen in Matz's careful tabulations of administrative reports on the number of marriages prevented in Württemberg in the mid-nineteenth century. He reports the number of marriages prevented as a percentage of marriages permitted. The resulting estimate displays huge cross-sectional variation. In Stuttgart the figure is 0.35 percent, while in some rural *Kreisen* it exceeds 9 percent (Matz 1984, pp. 204-6). But what does this mean? We do not know whether the 9 percent include couples applying for a second time, or couples who were denied permission the first time but were approved the next. We do not know how many people denied the right to marry in their home community simply migrated to another jurisdiction which they hoped might be more liberal. The 9 percent could *over-*estimate the number of couples who actually never married because of the *politische Ehekonsens*. Probably most important was the law's deterrent effect: we cannot know how many couples looked at the 9 percent, concluded that they themselves would also be denied the right to marry, and consequently never even applied.

A different way to approach the question is to ask what happened when the marriage restrictions were abolished. If they were binding constraints, we should see at least some immediate impact: a rise in marriage and a fall in illegitimate fertility. Knodel (1967) takes this approach. His study implicitly uses "differences in differences" to compare German states that had abandoned the *politische Ehekonsens* before 1871 to those, like Württemberg, that still had it when the Reich abolished the restrictions. His strategy only really shows how effective the *Ehekonsens* was in the years just prior to its repeal; marriage restrictions might have exercised a much lesser (or greater) effect in the eighteenth century. Knodel concludes that around the time of its abolition the *Ehekonsens* had measurable effects on both proportions

married and illegitimacy rates. Knodel's pioneering study relied on published, state-level data. Thus Württemberg is a single observation, one that implicitly averages large cities (where we know the *politische Ehekonsens* was enforced less strictly) with small communities of fewer than 2,000 inhabitants such as Auingen, Ebhausen, and Wildberg – the size of community in which a majority of the German population still lived into the late nineteenth century.³⁴

Our sources allow us to examine how the repeal affected behavior within an individual community, thus relying on a much sharper “before and after” design: we are looking at the same community under two different institutional regimes. Consider Figure 3 again. The repeal of the *politische Ehekonsens* was followed by marriage booms in all three of our communities. The number of marriages celebrated annually then fell to levels typical before the boom, suggesting that there was a stock of young people who had wanted to get married but could not do so because of the *Ehekonsens*. Once these people married, the volitional (i.e. informal) controls on marriage that Hajnal emphasized returned annual marriage counts to a lower level.

Figure 5 shows that the marriage boom also created a brief baby boom. This is the expected consequence of a large number of new marriages in a natural-fertility population. With age-specific marital fertility rates exceeding 500 for women in their twenties, we would expect every new marriage to produce a child every other year, over and above the births attributable to couples married before the end of the *Ehekonsens*. This baby boom also soon subsided, as the age-structure of the married population trended back toward what it had been under the old regime.

One interesting feature of Figures 3 and 5 is the difference between Auingen on the one hand and Ebhausen and Wildberg on the other. All three communities exhibited sharp reactions to the end of the *politische Ehekonsens*, but the effect seems more muted in Auingen. There are several potential explanations for the difference. The restrictions may have been enforced differently in Auingen before repeal; the outside opportunities for those prevented from marrying may have differed; or Auingen may

³⁴ In 1852, 67.3 percent of the German population lived in settlements under 2,000 inhabitants. See Twarog 1997, pp. 288-9.

have had a different local economic situation after repeal. The contrasting amplitude of the response to abolition of the marriage controls in different local contexts opens up intriguing avenues for deeper research.

A long tradition holds the marriage restrictions responsible for the unusual ubiquity of illegitimacy in south German societies. Indeed, Württemberg was a more moderate case than Bavaria, where Matz (1984, Figure 2) reports that 20-25 percent of all births in the mid-nineteenth century were illegitimate. In Württemberg as a whole, the figure was more like 12 percent in the 1830s and 1840s, rising to 16 percent in the late 1850s. As Matz emphasizes, the marriage controls in Bavaria were more severe, were explicitly retained in that territory after Bavaria joined the Reich, and were not abolished until 1916 (Ehmer 1991, p. 55). The historiography proposes several direct connections between illegitimacy and the *politische Ehekonsens*. One suggests that “outsiders” who were denied the right to marry had little reason to respect the norms of family life espoused by “insiders”; such women might bear illegitimate children with several different men because controlling their sexual urges would not in any case allow them to enjoy the settled family life and secure economic situation that such control offered “insiders.” Another argument implies that “outsiders” simply replicated the lives of “insiders” as best they could: often a couple that was denied the right to marry formed a “consensual union” and had a brood of children who would have been, had their parents lived elsewhere, legitimate.³⁵ Other women bore children before marrying; sometimes the husband was these children’s father, sometimes not.

The marriage restrictions did increase illegitimacy in our three communities. Figure 10 displays the impact on illegitimacy of the marriage restrictions’ repeal. The percentage of children born illegitimate declined by about one-half immediately, upon repeal, and stayed at a lower level for the rest of the nineteenth century. The immediate reduction in illegitimacy evident in Figure 10 does not support,

³⁵ The most famous version of this debate focused on Bavaria, but the same arguments are relevant for our communities. See Lee (1977, 1978) and Shorter (1971, 1973, 1978).

on its own, any particular interpretation of the relationship between the *Ehekonsens* and non-marital fertility, but the relationship's existence cannot be denied.³⁶

9. Conclusion

This paper provides an initial overview of a distinctive demographic regime observable in three Württemberg communities over a period of about three centuries ending in 1914. The populations we study are of particular interest because they lived under a set of economic, social, and demographic controls that were quite typical for central Europe but unknown in France, the Low Countries, or England, the European societies that have been the focus of most historical demographic research. These controls shaped demographic behavior both indirectly and directly, in ways that show up clearly even in these early results.

The pervasive regulation by local elites of the economic and demographic decisions of the lower social strata made Württemberg – including our three communities – poorer than other parts of western Europe, and less able to take advantage of the new opportunities offered by the growth of the European economy in the eighteenth and nineteenth centuries. This stagnant economy meant more out-migration and less opportunity to marry and form new households in one's community, or even one's country, of birth. Economic and demographic regulation in these central European communities effectively divided the population into "insiders" and "outsiders," forcing the latter to attempt to evade the pervasive restrictions on the life-choices they were allowed to make.

³⁶ One might expect the end of the *politische Ehekonsens* to result in a reduction in average ages at marriage. Tables 3-5 actually suggest such a reduction, excepting women in Auingen. But on closer examination the reduction in age at marriage during the quarter-century 1875-1899 took place long after the repeal of the *politische Ehekonsens*, and cannot properly be attributed to it. This is not the case in our reconstitutions (not shown); if anything, there is at first an increase in the number of older brides and grooms. This observation is consistent with the idea that the repeal's major effect was on a cohort of people in their twenties and early thirties who would not have been allowed to marry under the old regime, and who had been forced to wait to marry past the age when they would have preferred to do so.

These controls also exercised a direct impact on demographic behavior, with implications that show up starkly even in the simple measures we report here. The *politische Ehekonsens* had long required that couples wishing to marry obtain permission from local authorities. Permission was often denied, meaning that many young adults faced a choice between remaining single or leaving for other places. Some who remained had children anyway, but fewer than if they had been married. When these restrictions were removed between 1862 and 1870, an immediate marriage boom ensued, followed by an increase in the total number of births and a sharp reduction in the proportion of all children born to unwed mothers.

This dramatic reaction to the end of the state demographic controls in the late nineteenth century strongly suggests that the various precursor controls exercised on the local level over the entire earlier period exerted important and as yet unappreciated effects on demographic behavior. The regulations created a two-tiered demographic system. The upper tier consisted of those who could marry and enjoy full adulthood while continuing to live in this society: these “insiders” followed a demographic pattern characterized by high marital fertility but also unusually high mortality of their offspring, for reasons which we suspect to be economically endogenous but which require deeper investigation. The lower tier consisted of those who were denied access to marriage and the right to practise an occupation independently: these “outsiders” followed a demographic pattern characterized by epidemic emigration (for males), rising illegitimate fertility (for females), and high mortality among extra-marital “outsider” infants. The deeper operation of this “two-tiered” system in these Swabian villages, and its implications for demographic and economic development in central Europe over the three centuries before and during the transition to modern economic growth, open up perspectives for wider comparative analysis.

Appendix A: The Definition of Stillbirths

The definition of a stillbirth was probably neither standardized nor static in our communities, so some of the changes we observe may reflect changes in recording practices rather than (or in addition to) changes in the experience of late-term fetuses. There are two reasons for uncertainty about recording practices. First, religious concerns about the child's soul may have encouraged the baptism of children even if they were really stillborn. Lutherans (like Catholics) held that baptized children go to heaven, while unbaptized children do not. Adherents to such beliefs might baptize children who were actually stillborn.³⁷ Second, non-religious changes in the understanding of "birth" might lead to different judgments about an individual child.

The registers of baptism and burial for our communities include various notations that we have sorted into binary categories of "born alive" and "stillborn." Under "stillborn" we include children listed as "born dead", including the additional notation "premature" or "miscarriage", as well as "died shortly after birth." Several other notations suggest that a child was weak at birth or died soon after, but we do not include these in the stillbirth designation. These include indications that the child was given emergency baptism (*Gähtauf*, *Nottauf*), but did not die immediately; that the child was baptized at home or by the midwife or father, implying emergency baptism; that the child died shortly after birth or during an emergency baptism; or that the child was weak at birth (without there being any notation of death). Ours is a conservative parsing of the primary-source information, which is why we present results separately in the text using a broader definition of stillbirth. In practice, however, a more expansive reading of the primary sources would not give rise to appreciably different results. For example, we have coded children marked as "nameless" as not stillborn. One could make a case for these instances being ambiguous, but there is a total of 10 such births in Wildberg (out of a total of 15,509) and 35 in Ebhausen (out of 12,005). They cannot be a major source of estimation error.

³⁷ At least this belief is persistent in the historical demography literature; for example, Kintner (1987, p.237) claims "they [Catholics] tended to register stillbirths as infant deaths, thereby inflating the recorded infant mortality rate."

Notes:

Blank cell = registration has not yet started (see dates given in Table 1).

For first decade of recording, number of years is calculated from the date of the first entry to the end of the decade.

For decades in which gaps of over 6 months occur in baptisms or burials, number of years of recording is calculated by subtracting gap-periods from total years in decade.

Values for marriages have been arbitrarily set to values for baptisms.

Note: The table reports the proportion of all children born in a given month who died before reaching the age of one month.

Table 14: Estimates of the Coale-Trussell “M” and “m” for Auingen, Ebhausen, and Wildberg

Place	Couples married	“M” estimated as ASMR at 20 as a ratio of natural fertility standard	From nonlinear least squares		
			“M”	“m”	R ²
Auingen	1750-99	1.204	1.060 (.088)	-.374 (.068)	.99
Auingen	1800-49	1.358	1.089 (.168)	-.366 (.126)	.98
Auingen	1850-99	1.508	1.000 (.217)	-.691 (.161)	.98
Ebhausen	1750-99	1.186	1.113 (.060)	-.024 (.052)	.99
Ebhausen	1800-49	1.358	1.149 (.139)	.067 (.122)	.98
Ebhausen	1850-99	1.531	1.360 (.160)	-.002 (.114)	.98
Wildberg	1750-99	1.057	1.050 (.009)	.130 (.009)	.99
Wildberg	1800-49	1.161	1.175 (.024)	.289 (.024)	.99
Wildberg	1850-99	1.300	1.216 (.129)	.025 (.104)	.98

Note: The estimate of “M” in the third column is the marital fertility rate ages 20-24 divided by the Coale-Trussell natural fertility standard for those ages. The estimates in the last three columns are nonlinear least squares estimates of the model in levels. Standard errors are in parentheses. See text for discussion of the negative “m” values.
